Abstract

Chinese state-owned enterprises (SOEs) have become quite profitable recently. As the largest shareholder, the state has not asked SOEs to pay dividends in the past. Therefore, some have suggested that the state should ask SOEs to pay dividends. Indeed, the Chinese government has adopted this policy advice and started to demand back dividend payments starting from 2008. Although we do not question the soundness of the dividend policy, the point we raise is whether those profits are real if all costs owed by SOEs are properly accounted for: Among others, we are interested in investigating whether the profits of SOEs are still as large as they claim if they were to pay a market interest rate. Using a representative sample of corporate China, we find that the costs of financing for SOEs are significantly lower than for other companies after controlling for some fundamental factors for profitability and individual firm characteristics. In addition, our estimates show that if SOEs were to pay a market interest rate, their existing profits would be entirely wiped out. Our findings suggest that SOEs are still benefiting from credit subsidies, and they are not yet subject to the market interest rates. In an environment where credit rights are not fully respected, dividend policy, though important, should come second and not first.

I. Introduction

After many years of mounting losses, the latest data seem to indicate that Chinese state-owned enterprises (SOEs) are finally making profits. A World Bank (2005) study

* We wish to thank Hans Genberg, He Dong, and Matthew Yiu for helpful discussions and Angela Maria D'Uggento for offering her guidance to improve our sampling methodology. We acknowledge the useful comments provided by an anonymous referee, as well as by John Knight, May-Françoise Renard,

claims that SOE profit margins increased from 2.7 percent in 1999 to 5.7 percent in 2005, and growth in industrial profits averaged 36 percent over the same period. The study goes on to propose that the Chinese government should make an effort to cash in its dividends, which SOEs reportedly “forget” to pay out to their main shareholder. The World Bank study argues that this would be beneficial to China’s public finance and, more importantly, it would help rein in rapid investment growth in China by imposing more discipline on SOE managers.

These results have surprised many because the general impression has been that the majority of Chinese SOEs have low performance by international standards, as evidenced by the limited appreciation these firms obtain when listed in both the Hong Kong and overseas financial markets (Bai, Lu, and Tao 2006; Shan 2006). The World Bank study also appears to have ignored the fact that SOEs have not been consistent in honoring their obligations vis-à-vis bank debts, as SOE lending was perhaps the main source of non-performing loans (NPLs) at state-owned commercial banks (SOCBs) (Zhou 2004).¹ Therefore, one may question whether the profits are as high as reported if the costs of capital (not only including paying dividends to shareholders but also market-based interest rates to creditors) are properly accounted for. In addition, there are issues as to how much dividend the SOEs would have to pay to the government and whether the dividend policy could be at the expense of the health of the banking sector as long as SOCB creditor rights are not respected. Finally, continued inferior creditor right protection could significantly impair the improvement of SOCB corporate governance deriving from their diversified ownership, which was recently obtained with the stock exchange listings, thus leading to repeated write-offs of bad loans as experienced in some other transition economies should the economy experience a large downturn.

Indeed, before accepting the favorable interpretation put forward by the World Bank study and discussing dividend policy, one has to ask whether these SOE profits are real. Specifically, two issues need to be addressed. First, even though various analyses concur that SOE profitability has improved, the assessment is not always as rosy as in the World Bank study. OECD (2005) shows that SOE returns are significantly improving: For example, on average, in 2002–03, total factor

Changwen Zhao, and by several other participants at the 2010 Asian Economic Panel meeting in Seoul. The views presented in the paper are those of the authors alone and do not represent those of the institutions with which they are affiliated.

¹ Throughout the paper, for simplicity, we refer to the group consisting of the Industrial and Commercial Bank of China, Bank of China, China Construction Bank, and Agricultural Bank of China as the SOCBs. Though we are aware that three of these four banks have been listed on the stock exchange (Agricultural Bank of China is about to be listed at the time of writing) and the state is no longer the single shareholder (even if it still holds the majority).

productivity increased by 5 percent, delivering a return on assets (ROA) of 10 percent, twice as large as that in 1998–99. But the report is cautious to state that large pockets of weak SOEs remain.²

Second, another aspect deserving special attention is how bank debts are treated in calculating costs. It is well known that SOEs in China are quite reluctant to pay back their loans to SOCBs. This is because the relationship between SOEs and SOCBs was politically influenced and forbearance on debt has been the rule rather than the exception (Cull and Xu 2000, 2003; Brandt and Li 2003). These considerations raise doubts on whether the profits currently posted by China's SOEs are as high as reported or they could fade away once the generally accepted accounting principles are used.

Indeed, the preferential treatment accorded by SOCBs to SOEs can be grounded neither on SOEs' returns (which are noticeably lower than at private companies) nor on SOEs being less leveraged. Thus, it seems that SOEs do not entirely respect creditor rights.

The objective of this paper is thus twofold. First, we want to provide a careful assessment of Chinese SOEs' profits by adjusting for realistic interest service outlays. We first estimate the interest service outlays at market rates, benchmarking them also to Chinese private enterprises. We then use these estimates to impute what would be the "realistic" costs of bank debts for SOEs and compute the revised figures for profits. The resulting adjusted profits would provide a more credible assessment of SOE performance. As we will show, in spite of this adjustment, we still find that there has been an improvement in SOE profitability over recent years.

The second issue we address is a policy one. That is, whether China's government would be better served by encouraging SOCBs to improve their lending practices rather than just cashing in SOE profits. As it stands—even after the successful stock exchange listings of China Construction Bank, Bank of China, and Industrial and

2 Specifically, the report finds: (1) Performance is best where the state controls the company through a large minority stake, or where state ownership is intermediated (i.e., at indirectly state-controlled firms, with state legal person controlling shareholders); and it is the worst at directly state controlled companies. (2) Although private Chinese and listed SOEs compare quite favorably (though there is a visible bias to listing best performing SOEs), an international comparison of enterprise rates of ROA still ranks the Chinese median firm return the lowest in a group of the worst performing OECD and non-OECD economies. (3) Two-thirds of state held firms in the industrial sector earn less than a 5 percent rate of return on assets prior to payment of interest and nearly 15 percent of state-controlled industrial companies trade with negative equity funds. (4) Distressed companies now represent 7 percent of firms, 11 percent of workers, 23 percent of assets, and 22 percent of outstanding debts.

Commercial Bank of China—the government is the main shareholder at both SOEs and SOCBs. As such, the government might consider that stiffening credit policies by SOCBs may be more effective than simply cashing in SOE dividends. Indeed, as finance theory postulates, shareholders should be residual claimants on firms' profits only after all creditors are duly paid. In other words, SOCBs have a priority claim on SOE profits and the government could take this opportunity to encourage SOCBs to improve their credit management vis-à-vis SOEs. More importantly, by re-asserting creditor rights, this would further improve the credit culture and the market economy in general in China.

The rest of the paper proceeds as follows. Section 2 recaps the relevant literature at the heart of the debate on whether and to what extent Chinese SOEs have become profitable. Here, we also summarize the issue of policy-influenced loans to induce SOCBs to keep lending on favorable terms to SOEs. Section 3 outlines the methodology we employed to build a representative sample. Section 4 is devoted to the empirical analysis by first presenting some preliminary descriptive findings and then performing our regression analysis to come up with accurate estimates of the loan rate subsidy SOEs appear to enjoy. Section 5 computes the adjusted profits for SOEs and shows that, after making SOEs pay loan rates on par with otherwise equivalent private enterprises, SOE profits are entirely wiped out on the average of the reference period. Based on these calculations, Section 6 discusses policy implications and concludes.

2. The landscape of the Chinese corporate sector and a literature review

Since the mid 1990s, the landscape of the Chinese corporate sector has experienced significant changes. From a database of firms with annual sales of 5 million yuan maintained by the National Bureau of Statistics of China (NBS), we find that the share of private enterprises in the total number of enterprises has increased from 6.5 to 45 percent and the share in total value-added from 2.6 to 18 percent from 1998 to 2005. The SOE share and its share in total value-added decreased rapidly, respectively, from 39.2 to 10 percent and from 57 to 37.6 percent. An OECD (2005) study shows that, according to pre-tax returns on equity (ROE), private firms are generally more profitable than SOEs, although SOEs' profitability is also on the rise. In addition, private firms have a lower level of indebtedness (measured as a percent of their assets) and a lower debt/equity ratio as compared to state firms. Nonetheless, debt/equity ratios are decreasing for both private and state-owned enterprises.

Despite being more profitable, private companies continue to face difficulties in their access to bank credit. According to the same OECD study, about 41 percent of private enterprises have no access to credit and 56 percent have no access to bank

Table 1a. Profitability of Chinese enterprises by ownership

	ROA		ROE	
	1998	2003	1998	2003
All enterprises	6.1	12.2	3.8	12.2
State-owned enterprises	4.8	10.2	2.0	10.2
Collective enterprises	11.2	16.5	10.8	16.5
Private enterprises	7.8	15.0	6.0	14.4

Source: OECD, *Economic Surveys, China*.

credit. Smaller private enterprises are even more constrained than other firms. For private firms, major hurdles are a lack of collateral and ownership discrimination. Even though their access to bank financing is improving with a 67 percent increase in lending between 1998 and 2003, private companies are still financially constrained.

Public ownership in the banking and industrial sectors appears to be one of the key factors behind the fragility of Chinese banking. Two statistics are revealing: although SOEs' contribution to the Chinese GDP was around 25 percent, they received about 65 percent of total loans. In addition, the ROA and ROE of private companies are higher than those of state enterprises (see Table 1a).

Another aspect deserving special attention among the factors determining SOE profits is how bank debts are treated in calculating costs. It is well known that SOEs in China are quite reluctant to pay back their loans to SOCBs. This is because the relationship between SOEs and SOCBs was politically influenced and forbearance on debt has been the rule rather than the exception (Cull and Xu 2000, 2003; Brandt and Li 2003; Héricourt and Poncet 2009). These considerations raise doubts about whether the profits currently posted by China's SOEs are as high as reported or if the profits could fade away once the generally accepted accounting principles are used. A simple calculation using the data published by the OECD (2005) helps exemplify this point. By taking the ratio of the interest outlays to debt outstanding, we impute the implicit interest rate companies pay to creditors. Imputed interest rates on debt are significantly lower for SOEs with respect to private companies and the difference does not disappear over the years (see Table 1b).

Indeed, such preferential treatment accorded by creditors to SOEs can be grounded neither on SOEs' returns (which, as seen, are noticeably lower than at private companies) nor on SOEs being less leveraged (the debt gearing ratio measured as stock of debt over value-added is visibly larger at SOEs and the difference is, if anything, increasing; see Table 1b). Although requiring more careful study, this evidence

Table 1b. Imputed interest rates on debt and gearing ratios of enterprises by ownership

Imputed interest rates on debt	1999	2000	2001	2002	2003
SOEs (a)	5.06	4.68	4.31	4.26	3.92
Private enterprises (b)	6.44	5.83	5.65	5.49	5.23
Difference (a) – (b)	-1.38	-1.15	-1.34	-1.23	-1.31
Gearing ratios					
SOEs (c)	302.20	252.20	238.90	222.90	193.90
Private enterprises (d)	122.70	108.00	92.00	80.10	72.70
Ratio (c) / (d)	2.46	2.34	2.60	2.78	2.67

Source: Our calculations on data from OECD, *Economic Surveys, China*.

seems to be consistent with the hypothesis that SOEs do not entirely respect creditors' rights.

These descriptive analyses are also confirmed by more rigorous statistical analyses. Xiao (2006), using the NBS data set of over 20,000 large and medium-sized firms for the period 1995–2002 and adjusting for firm characteristics and fundamentals, finds that SOEs are still much more likely to generate bad debts for the banking system than non-state enterprises despite the fact that non-performing debts in SOEs have been falling since 2000. Bai, Lu, and Tao (2006) use the same data set but a different sample period ranging from 1998–2003 to investigate whether privatization or ownership change brings about economic and social efficiency. They find that ownership reform helps increase economic efficiency in those reformed firms. Specifically, Bai et al. attribute the reduction of agency costs, measured by the ratio of administrative costs, to the improvement of economic efficiency. Using a different survey data set with 12,400 firms in 120 Chinese cities conducted by the World Bank, Dollar and Wei (2007) also find that state-owned firms have low marginal returns to capital relative to private and foreign firms. Such efficiency losses amount to 5 percent of GDP if SOEs can improve financial controls and corporate governances further.

Although these existing studies shed light on SOE performance, they do not address the issue of whether the profits of SOEs are real after other costs are accounted for, especially interest rate costs. We focus on this issue in the following sections.

3. Data, sampling methodology, and descriptive statistics

Our data sample is obtained from the NBS database, which contains more than 280,000 industrial firms with annual sales above 500 million yuan. It is estimated that the firms included in this census represent about 80 percent of all industrial value-added activities among Chinese firms. For yearly data we use approximately 69 financial indicators including, asset, liability, revenue of major activities, profits,

value-added taxes, intermediate industrial input, cash flows, debt payments, and other indicators that allow us to conduct our analysis. Given that there are some major discrepancies in certain financial indicators for data before 2000, we start our data sample from 2001 to avoid such problems. In addition, given that it was impossible for us to obtain the whole database, we use a sampling methodology to construct a representative sample to reflect the NBS database.

Our sample was constructed by following two methodological rules. First, we extracted a random component designed to make a closed sample of Chinese enterprises. Second, because of a large number of firm drop-outs, which resulted from enterprises' birth and disappearance and/or from merger and acquisition (M&A) activity as well as statistics that were discontinued by the NBS, we superimposed the closed sample component over an open sample component. The latter component was randomly extracted.

The closed sample component was built according to the following considerations and methodology. To respect the bounds represented by the necessity to minimize costs and time, we determined the dimension of the sample (n) on the basis of the financial resources of the research/project and of the tolerable error, with a confidence level of 95 percent. We obtained a sample composed of 5,497 units based on the following formula:

$$n = \frac{z_{\alpha/2}^2 N}{\{(N-1)\theta^2 / P(1-P)\} + z_{\alpha/2}^2},$$

where n is the number selected for the sample size; z is a standardized variable with mean 0 and variance 1; $1 - \alpha$ is the degree of trust; N is the total number of units in the population to be sampled; θ is the allowed error size; and P is the unknown proportion, which we set at 0.5.

To select the statistical units, we used a stratified random sampling method that provides greater precision and gives a better representation of the original population than a simple random sample of the same size. Moreover, providing greater precision, a stratified sample generally requires a smaller sample size, although this advantage is achieved at the cost of more administrative and operative efforts compared to the simple random sample.

In this perspective, with reference to the 2001 data, we divided the population of 211,181 firms (N) into 14,250 strata, deriving from the combination of four stratification variables that we considered the most relevant for the aims of the research. The stratification variables are:

- Province (30 sub-strata);
- Ownership (5 sub-strata: SOE; cooperatives; private enterprises; enterprises with capital from Hong Kong and/or Macau and/or Taiwan; foreign-owned enterprises);
- SITC Sectors (19 sub-strata);
- Size of employment (5 sub-strata: 0–99 employees; 100–299 employees; 300–499 employees; 500–999 employees; 1,000 employees and above).

On the basis of these stratification variables, starting from the distribution of the population of the firms (N), we defined the sample design using a proportional to size allocation technique. According to this method, the frequencies of the statistical units in each stratum of the stratified sample are proportional to those of the stratified population. In other words, with proportional stratification, the sample size of each stratum is proportional to the population size of the stratum and this means that each stratum has the same sampling fraction. This technique is based on the assumption that selection costs and variances are about equal across strata.³

To overtake the practical problem of the proportional selection from the population strata containing a low number of firms, we introduced a cut-off value that excludes all the cells with a frequency less than 14 units (that means 0.008 percent of the population) from the selection. The allocation of the 5,497 units of the sample among the strata is shown in Tables 5 and 6 hereafter.⁴ The final sample (n) is formed by summing the random samples obtained from each stratum. Finally, because our research question regards the specificity of SOEs, we oversampled SOEs within each stratum.

The open sample component was then added to the observations extracted to form the closed sample. The superimposition of this additional component should also help minimize our sampling error.

The composition of the total sample by ownership class is described in Appendix 1. The second column reports the percentage shares in the a priori base closed sample and the third column shows the shares in the a priori total sample, that is, after oversampling SOEs and after superimposing the open sample component. Columns (4) to (8) report the actual shares in the ex post total sample. It is possible to notice

3 The advantages of proportional stratification are: (1) it provides equal or better precision than a simple random sample of the same size; (2) the gains in precision are greatest when values within strata are homogeneous; and (3) the gains in precision accrue to all survey measures.

4 The number of observations within each stratum N_h is known, and $N = N_1 + N_2 + N_3 + \dots + N_{H-1} + N_H$.

that the ex post shares are reasonably close to the a priori ones. Only the SOEs are slightly under represented. Finally, the size of the sample is on average near that of the a priori desired number, however observations are somewhat under-sampled in year 2004 and somewhat over-sampled in 2005.

4. Empirical analysis

Our empirical analysis hinges on estimating the costs of debt for SOEs and comparing them to what we found for the other ownership classes, particularly for private enterprises. We construct two different proxies to measure the costs of debt:

$$\text{intrate}_{it} = \text{intpay}_{it} / \text{totdebt}_{it} \quad (1)$$

$$\text{intrate1}_{it} = \text{fincost}_{it} / \text{totdebt}_{it} \quad (2)$$

where intpay_{it} is the interest payment for firm i in year t ; totdebt_{it} is the total debt for firm i outstanding at the end of year t ; and fincost_{it} is the total financial costs for firm i in year t .

Even though the proxy in equation (1) is the appropriate measure of the interest rate, the proxy in equation (2) may be a better measure of the total costs of debt because it also includes non-interest costs. For our purposes, it makes sense to consider both proxies.

Before moving to the econometric analysis, we present some descriptive evidence on the two proxies and on other basic performance measures. According to our interest, all of these measures are broken down by ownership class.

4.1 Descriptive statistics

The perception that SOEs pay lower rates is confirmed at the descriptive level. This is true irrespectively of whether we consider intrate or intrate1 . The average data for intrate are reported in Table 2a, while those for intrate1 are shown in Table 2b.

With respect to intrate , SOEs paid 133 basis points less than the total sample average during the sample period from 2001–05. The SOE gap amounts to 265 basis points with respect to cooperative enterprises and 198 basis points compared to private enterprises. However, intrate for SOEs does not seem to differ significantly from two other special classes of enterprises—those with ownership located in Hong Kong, Macau, and Taiwan and those with ownership located outside of greater China. Therefore, lower costs of debt for SOEs, especially with respect to private firms, is mostly systematic across the years.

Table 2a. Estimated interest rate by year and ownership— $\text{intrate} = \text{intpay} / \text{debt}$

	SOE (tot)	Coop	Private	HK-Macau-Taiwan	Foreign capital	Total
2001	2.46	4.94	4.84	2.89	2.98	4.13
2002	2.23	4.65	4.64	2.81	2.61	3.92
2003	2.67	5.38	4.61	2.59	2.28	3.93

2001–03	2.65	5.70	4.99	2.70	3.35	4.24
2004–05	2.58	12.45	4.69	2.87	3.41	4.10

Source: Authors' calculations based on our own database.

Note: Interest rates are calculated as the ratio of finance costs in the year to total debts outstanding at the end of the year. We excluded outlying firms with negative finance costs or with $\text{intrate1} > 100\%$.

We reach similar results after examining intrate1 . With respect to the entire period, SOEs pay 157 basis points less than the average company, 225 basis points less than private enterprises, 4 basis points less than Hong Kong, Macau, and Taiwan companies, and 75 basis points less than foreign capital firms. Note that the favorable gap for SOEs does not reduce visibly over time.

The low costs of debt for SOEs seem to be neither justified on the grounds of better profitability nor on the basis of lower leverage, where both variables affect the probability of default—negatively for the former and positively for the latter. The basic measure of profitability we consider is ROA, given by the ratio of total profits to total assets.

From Table 3a, we notice that average ROA increases by approximately 1 percentage point (from 6.26 percent in 2001–03 to 7.24 percent in 2004–05) while reaching 6.66 percent on average, a relatively low value by international standards. However, profitability varies noticeably across ownership classes from the highest levels

Table 3a. ROA by year and ownership

	SOE (tot)	Coop	Private	HK-Macau-Taiwan	Foreign capital	Total
2001	-1.09	9.67	8.54	3.49	5.62	6.05
2002	-0.98	9.44	8.13	3.66	5.24	5.86
2003	-1.07	13.48	9.04	4.26	6.54	6.80

Note: ROA is calculated as the ratio of the sum of profits within the class to the sum of total assets within the class.

reached by private firms (9.23 percent and increasing between the two sub-periods) and cooperative enterprises (10.88 percent), to the intermediate values for Hong Kong-Macau-Taiwan companies (3.70 percent and slightly decreasing between the two sub-periods) and foreign capital firms (5.82 percent and stable), to the minimum of SOEs, which record persistently negative levels (-1.23 percent for the entire period, worsening from -1.05 to -1.54 percent across the two sub-periods). Nevertheless, judging the SOE sector performance on this per capita level would be misleading if, as it happens, the improvement in performance is achieved mostly by the larger SOEs.

To be sure, we should remark that if we use a weighted average, the ROA for SOEs is no longer negative: It is 0.92 percent over 2001-05 and, even though remaining well below those for the other ownership classes, shows some improvement from 0.77 percent in 2001-03 to 1.14 percent in 2004-05 (Table 3b).

Table 3c reports the leverage ratio, defined as the ratio of total debts over total liabilities. The sample average suggests that leverage increases only slightly from 59.46 in 2001-03 to 59.93 percent in 2004-05 and averaged 59.65 percent over the entire period, which is a relatively high value by international standards. In addition, lever-

Table 3c. Leverage ratio by year and ownership

	SOE (tot)	Coop	Private	HK-Macau-Taiwan	Foreign capital	Total
2001	67.80	62.95	62.25	55.72	53.92	61.01

age is systematically higher for SOEs and has increased over the years. Foreign-funded firms have the lowest leverage at 52.59 percent, followed by the Hong Kong-Macau-Taiwan companies at 55.13 percent, private firms at 60.25, cooperative enterprises at 60.86 percent, and SOEs at 68.49 percent.

Obviously, the low costs of debt for SOEs might be explained by other factors. For instance, a major expected difference between the SOEs and private enterprises is asset size, whereby creditors might grant lower borrowing rates to SOEs because their large asset size can be utilized for collateral and makes them less likely to default. Indeed, asset size differs noticeably across ownership classes (Table 4a). Typically, SOEs are more than twice as large as foreign-owned firms, almost four times as large as enterprises receiving capital from Hong Kong-Macau-Taiwan, and more than ten times as large as cooperatives or private firms.

The employment number may be another indicator. As shown in Table 4b, against the overall average number of 208 per-firm employees, SOEs are twice the average (453), whereas Hong Kong-Macau-Taiwan and foreign-funded companies are in the

Note: Interest rates are calculated as the ratio of interest payments (finance costs) in the year to total debts outstanding at the end of the year. To come up with the average values reported in the table, we excluded some outlying firms with negative interest payments (finance costs).

intermediate ranking with 306 and 273 employees, respectively. Cooperatives have 144 employees and private enterprises have 114 employees and are placed at the bottom of the ladder.

Indeed, the data confirm that the costs of debt are noticeably lower as firm size increases. Table 4c reports the interest rates according to our two definitions. The drop in the costs of debt is particularly visible as firm size moves beyond 85 employees, which is the median value in the sample.

Another consideration is the industrial sector. SOEs are traditionally concentrated in sectors that may require economies of scale as a natural monopoly. Specialization in these sectors might also induce lenders to perceive lower probabilities of default for SOEs. Indeed, as shown in Table 5, the degree of over-representation of SOEs is largest in tap water production and supply and in electric power, steam, and hot water. These two sectors comprise approximately one-third of the total SOEs in our sample and it is worth noticing that the cost of debt in these two sectors—2.76 and 2.94 percent, respectively—is far below the average (3.88 percent).

Finally, the costs of debt may also vary across provinces where, at times, the level of economic development is low, the degree of privatization is small, the industrial

structure is highly concentrated in heavy or resource-oriented industries, and foreign presence is minimal. As shown in Table 6, SOEs are at least twice as represented with respect to the overall sample in 17 provinces, in decreasing order: Xizang, Qinghai, Xinjiang, Shaanxi, Gansu, Heilongjiang, Guangxi, Guizhou, Jilin, Shanxi, Beijing City, Yunnan, Jiangxi, Tianjin, Liaoning, Hunan, and Nei Mongol, mostly in the western and northeastern heavy industry hinterland. It is important to highlight that in 13 of these 17 provinces the average cost of debt is below—often much below—the national average.

Although these simple statistical analyses may be revealing, an econometric framework is still required to show whether this is indeed the case empirically.

Specifically, we need to control for profitability, asset size, firm size, industrial sector, and the location of each enterprise. We turn to the empirical framework in the following sub-section.

4.2 Econometric results

In line with the previous discussion, the regressions we estimate have the following form:

$$y_{it} = \alpha + \beta_1 \text{SOE}_{it} + \beta_2 \text{COOP}_{it} + \beta_3 \text{HKMTW}_{it} + \beta_4 \text{FORK}_{it} + \beta_5 \text{SECTOR}_{it} + \beta_6 \text{PROVINCE}_{it} + \beta_7 X_{it} + \varepsilon_{it}, \quad (3)$$

where the dependent variable y_{it} will alternatively be intrate_{it} or intrate1_{it} ; SOE, COOP, HKMTW, and FORK are dummies taking value 1, respectively, for SOEs, cooperatives, companies owned from Hong Kong-Macau-Taiwan, and enterprises with ownership outside of greater China, and taking value 0 otherwise. Here the omitted variable is PRIV, which is the dummy for private enterprises. SECTOR is a

vector of 0–1 sectoral dummies and PROVINCE is a vector of 0–1 locational dummies. Here, several insignificant sectors (provinces) are omitted. X_{it} is a vector of variables that control for economic fundamentals that may affect the costs of debt. These variables include asset size or employment size, and history of the enterprise.⁵ Index i refers to the firm, and t runs from 2001 to 2005 for the estimation on the entire sample, from 2001 to 2003 for the estimation on the first sub-sample, and from 2004 to 2005 for the estimation on the second sub-sample.

We ran three panel regressions—similarly for *intrate* and *intrate1*—with the first one estimated over the entire period 2001–05, the second focusing on the 2001–03 sub-period, and the third estimated over the 2004–05 sub-period. All estimates were performed using a generalized least squares panel specification with random effects and robust standard errors. The choice of the random effects estimation must be justified because if we were to adopt it for a sample that should instead be estimated via fixed effects our estimates would be inconsistent. Our choice is motivated by three considerations. First, the number of the observations in the sample for each year is rather large (the minimum is 5,597 in 2004, and the maximum is 9,276 in 2005). Second, under the alternative fixed effects specification, regressors other than the constant term were generally insignificant and the fit of the model was really poor. Third, the Hausman test often suggested that the fixed effects model should be rejected.⁶

Table 7 shows the results for *intrate*, and confirms our expectations. Larger enterprises have lower costs of debt. In addition, with respect to ownership, even after controlling for size, location, and productive specialization, SOEs, Hong Kong-Macau-Taiwan firms, and foreign-owned companies still pay lower loan rates compared to private companies (i.e., the omitted ownership dummy), and no significant difference is detected for the cooperatives. To be sure, the debt costs gap compared

-
- 5 We also attempted specifications by including profitability (ROE and ROA) and leverage, but the results turned out with the “wrong” sign, that is, negative on profitability and positive on leverage. This would seem to imply a soft budget constraint whereby creditors are enforcing higher payments on enterprises that can afford them. While postponing further analysis to future work, for the moment, we decided to discard these performance variables.
- 6 As the values of the Hausman test reported in the tables will show, rejection was achieved at rather comfortable confidence levels for *intrate* regressions. This was not the case for the *intrate1* regressions where the Hausman test suggested rejection of the fixed effects model at a comfortable level for the 2004–05 sub-period, and for the total 2001–05 sample; on the contrary, according to the Hausman test, the fixed effects specification could not be rejected for the 2001–03 sub-period. Nevertheless, we opted for the random effects model for the *intrate1* regressions in light of the fact that the Hausman test can be misleading when the fixed effects model has a poor fit since the matrix may not be positively definite.

to private enterprises is largest for SOEs, intermediate for foreign-owned companies, and lowest for Hong Kong-Macau-Taiwan firms. The cost of debt for SOEs is lower than for otherwise equivalent private companies by 221 basis points over the entire period. While this gap decreases somewhat (54 basis points) between the first sub-period 2001–03 and the second sub-period 2004–05, it still runs at 188 basis points in the later sub-period. Thus, the distortion coming from the credit market is certainly not trivial.

The results for *intrate1* are also consistent with our a priori (see abridged results in Table 8). Firm size implies lower interest rates while SOEs, Hong Kong-Macau-

Taiwan firms, and foreign-owned companies enjoy a lower cost of debt with respect to private companies. Finally, here the gap compared to private enterprises is largest for SOEs, intermediate for Hong Kong-Macau-Taiwan firms, and lowest for foreign-owned companies. Interestingly, the results obtained for *intrate1* in terms of the dynamics of the gap, which is on average 254 basis points, show no evidence of a reduction over time, which is something that was instead observed for the estimates on *intrate*.

5. Revised SOE profitability: An estimate

Revised SOE profits were computed according to the following methodology. In practice, we augmented the interest payment (financial cost) variable by means of the value of the coefficients estimated in the regression. In turn, we considered two types of corrections—the interest rate estimated for private enterprises, and the interest rate estimated for foreign capital enterprises. Thus, for instance, according to the private enterprise correction, SOEs' interest payments (according to the *intpay* method) are increased for the entire 2001–05 period by 86.5 percent because the estimated coefficient is -0.02209 , which is exactly 86.5 percent of SOEs' actual cost of debt (0.02552). In turn, referring to the foreign capital enterprise correction, SOEs' interest payments (according to the *intpay* method) are increased for the entire 2001–05 period by 32.0 percent since the coefficient estimated for the foreign capital enterprises (-0.01391) is subtracted from the coefficient estimated for the SOEs (-0.02209) thus delivering 0.00818, which is exactly 32.0 percent of SOEs' actual cost of debt. The same method is applied to the other sub-periods and also, *mutatis mutandis*, to *intrate1*. By doing this, we are putting SOEs on the same par with private companies or with foreign capital enterprises.

Next, we calculate the ratio of the additional interest payment (financial cost)—what SOEs should pay were they treated as private firms—to the observed SOEs' total profits. The results of these calculations are reported in Table 9.

According to our calculations, SOEs' profits would have been entirely wiped out if SOEs were made to pay the same interest rates as otherwise equivalent private enterprises. Over the entire sample period, the percentage of SOE profits dented by the correction to their cost of debt is 155.9 and 171.8 percent of profits, respectively, depending on whether we refer to *intrate* or *intrate1*. The only good news is the observation that the percentage drops significantly moving from the first sub-period 2001–03 to the second. Nevertheless, even in the second sub-period (2004–05), 92.5 percent of the profits would be cancelled according to the *intrate* method and even more following the *intrate1* method.

Table 9. Percentage of SOE profits denoted by applying their private enterprise interest rates

Year	Private enterprise interest rates		Foreign capital enterprise interest rates	
	Intpay method (<i>Intrate</i>)	Finco method (<i>Intrate1</i>)	Intpay method (<i>Intrate</i>)	Finco method (<i>Intrate1</i>)
2001–05	155.9	171.8	57.7	112.5
<i>Memorandum items:</i>				
2001–03	221.7	214.8	91.3	134.2
2004–05	92.5	127.7	23.8	93.2

Note: Based on panel random effects estimates with robust standard errors.

If, instead of imputing private enterprise interest rates, we charge SOEs the interest rates estimated for foreign capital enterprises, the drop in SOE profits is still huge. Over the entire 2001–05 period, the drop amounts to 57.7 and 112.5 percent according to the intpay and finco methods, respectively.

6. Conclusion

This paper investigated whether the profits of SOEs in China are real using a data set that is representative of corporate China (i.e., the $\pm 250,000$ firms with annual sales over 50 million yuan) for the period 2001 to 2005 by China's NBS. Our empirical findings suggest that SOE profits might be overstated because SOEs have historically benefited from subsidized bank credit. Owing to political interference inducing state-owned commercial banks (SOCBs) to lend to them, SOEs were hardly disciplined by lenders. Although SOE losses were the major source of SOCB NPLs, it is common knowledge that even those SOEs repaying their loans do so on favorable terms. Thus, subsidized loans to SOEs contribute to a large extent to maintaining SOCBs' poor profitability track record and, through that, cause repeated capital injections in the SOCBs by the government.

Within our framework, the paper made three contributions. First, we constructed a representative sample of corporate China where SOEs are oversampled purposely to allow more precise identification of their peculiarities compared to other Chinese enterprises. Second, using that sample, we proved that, indeed, the cost of debt is significantly lower for SOEs, even after controlling for individual firm features. Third, we estimated that should SOEs pay the same loan rates as otherwise equivalent private enterprises, their additional interest outlays would be larger than SOE profits on average from 2001–05 and—even though decreasing relatively—the additional interest payment would still wipe out all SOE profits from 2004–05, the most recent years in our sample. And even charging SOEs the same interest rates esti-

mated for foreign capital enterprises—thus making the hardly tenable assumption that the ability/willingness to honor debt obligations is the same for the two classes of companies—the SOE profits would at least halve if not vanish.

Accordingly, it seems that safeguarding creditors' rights should be the utmost priority. This means inducing SOEs to pay market interest rates on (and to service scrupulously) their loans. Through that, SOCB performance would improve greatly—in a way consistent with the new incentives after the stock exchange listing of three of the four SOCBs—and the state would save further recapitalization. In addition, in this case, SOE managers would undergo creditors' discipline, to which the discipline exerted by dividends could be added should profits still remain positive after adequate loan servicing.

Overall, our results suggest that strengthening creditors' rights should be the primary step in the process to complete transition to a market economy in China by bringing SOEs under more strict discipline. Dividend policy should come second and not first.
